

Two faces of one optimum: wobble error-resistance and minimal tRNA decoding coincide in the genetic code

Jonathan Reich

Abstract

The standard genetic code is “optimal” in two separate literatures: it is highly error-resistant, and it is decoded by a remarkably small set of tRNAs. We prove these are the same optimum: the wobble-fibre constancy that uniquely maximises the third-position silent-edge count—the dominant component of single-substitution error-resistance—also uniquely minimises the number of tRNAs needed to decode the code under superwobble. The minimiser of the decoding number is exactly the maximiser of silent edges. Because this coupling is specific to superwobble (the four-way decoding by which organelles and reduced genomes use minimal tRNA sets), it predicts that decoding redundancy above the minimum grows with genome size—confirmed across 390 genomes ($p \approx 6 \times 10^{-10}$, phylogenetically controlled). If one structural property yields both error-resistance and decoding economy, neither need be the other’s selective cause, and the adaptive-versus-neutral debate is, for this component, ill-posed.

Significance. Why the genetic code is so resistant to mutation is a classic question, answered either by selection for error-tolerance or by appeal to neutral evolution. We prove a theorem that makes the dispute moot for a major component of robustness: the feature that renders the code maximally error-resistant under third-position mutation—grouping codons into four-codon families—is *identical* to the feature that lets it be decoded by the fewest possible tRNAs. Error-resistance and translational economy are one optimum, not two. The link is realised through superwobble decoding, and we confirm its population-level signature across 390 genomes spanning all domains of life.

1 Introduction

The near-universal genetic code is redundant in a strikingly non-random way. Two features have each been called optimal. First, *error-resistance*: synonymous codons differ predominantly at the third (wobble) position, so most single-nucleotide substitutions are silent or conservative, and the code beats almost all random codes on error-load measures [8, 9]. Second, *decoding economy*: although there are 61 sense codons, organisms read them with far fewer tRNA species—31 at the Crick minimum [2], and as few as 22 in animal mitochondria—by exploiting wobble pairing at the anticodon [5, 6]. These two optimalities have been studied independently, with error-resistance framed in terms of amino-acid assignment and decoding economy in terms of tRNA modification and gene content.

Here we show they are not independent: they are two expressions of the same combinatorial property. A companion result [1] proves that the third-position silent-edge count S_3 is uniquely maximised by *wobble-fibre constancy*—making each two-base codon prefix wholly synonymous

(a four-codon family box). We prove that wobble-fibre constancy also uniquely *minimises* the number of tRNAs required to decode the code under superwobble reading [7]. The argmin of the decoding number equals the argmax of S_3 (Theorem 1). The result is exact, elementary, and machine-verified, and it has a sharp biological corollary: because the coincidence holds under four-way superwobble (Remark 1)—the regime in which organelles and reduced genomes actually decode whole family boxes with single, unmodified tRNAs [7]—the lineages in which robustness and economy are *jointly* optimised are exactly the reduced, superwobble-using genomes, while expanded cytoplasmic repertoires, decoding through modified wobble, sit further from the optimum. We confirm the resulting prediction—that decoding redundancy above the minimum grows with genome size—in a 390-genome, phylogenetically controlled comparative survey.

The conceptual payoff speaks to one of the oldest questions about the code. Freeland and Hurst’s demonstration that the standard code beats almost all alternatives on error load—“one in a million” [8, 9]—is widely read as evidence of selection *for* mutational robustness; a neutralist tradition counters that robustness emerged as a by-product of code expansion and tRNA coevolution [10, 11]. The dual optimality shows the framing is under-determined. A single structural property—large family boxes—yields error-resistance and a minimal decoding apparatus simultaneously, so any force that enlarges family boxes (selection for tRNA economy, genome reduction, biased substitution) delivers error-resistance for free, and conversely. Optimality in one currency *is* optimality in the other; neither need be the proximate target of selection.

2 Results

2.1 The silent-edge functional and the decoding number

Let $\mathcal{C} = \{A, C, G, U\}^3$ be the 64 codons; a *code* is a map $f: \mathcal{C} \rightarrow \Sigma$ onto the 20 amino acids and **Stop**. Two codons are adjacent if they differ at one position; an edge is *silent* if its endpoints share f . Let $S_3(f)$ count silent edges whose substitution is at the third position. Writing $\pi(c)$ for the two-base prefix of c , the 16 prefixes partition $\mathcal{C}$ into *boxes* of four codons, and two codons share a prefix iff they are third-position-adjacent; hence the third-position adjacency graph is 16 disjoint copies of K_4 . With $n_{\pi,a} = \#\{c: \pi(c) = \pi, f(c) = a\}$,

$$S_3(f) = \sum_{\pi} \sum_a \binom{n_{\pi,a}}{2}. \quad (1)$$

A tRNA charges one amino acid and reads codons that differ only at the third position, i.e. within one box. Under *superwobble* a single modified anticodon can read any subset of a box’s third positions [5, 6]; thus one tRNA decodes each non-empty (π, a) group ($a \neq \mathbf{Stop}$), and the minimal decoding number is

$$D_{\text{sw}}(f) = \sum_{\pi} m_{\pi}, \quad m_{\pi} = \#\{a \neq \mathbf{Stop} : n_{\pi,a} > 0\}. \quad (2)$$

Under strict Crick wobble a single anticodon reads only certain pairs, and a four-codon family costs two tRNAs; we return to this in Remark 1.

2.2 Dual optimality

Lemma 1 (Per-box monotonicity). *Within a box, merging two amino-acid groups of sizes a, b raises that box’s contribution to S_3 by $ab > 0$ and lowers its contribution to D_{sw} by 1. Hence, per box, S_3 is maximised iff D_{sw} is minimised, at the monochromatic partition.*

Proof. By (1) the box contributes $\sum_i \binom{k_i}{2}$; $\binom{a+b}{2} - \binom{a}{2} - \binom{b}{2} = ab$. By (2) it contributes its number of groups, which falls by 1 on a merge. $\square$

Theorem 1 (Dual optimality). *For every code, $D_{\text{sw}}(f) \geq 16$ and $S_3(f) \leq 96$, and the following are equivalent: (i) $D_{\text{sw}}(f) = 16$; (ii) $S_3(f) = 96$; (iii) f is wobble-fibre constant. Consequently $\arg \min_f D_{\text{sw}}(f) = \arg \max_f S_3(f)$: the minimal-tRNA codes are exactly the maximally wobble-robust codes.*

Proof. Each of the 16 boxes contributes ≥ 1 to D_{sw} and $\leq \binom{4}{2} = 6$ to S_3 , both extremes reached together iff the box is monochromatic (Lemma 1). Sum over boxes. $\square$

Remark 1 (Superwobble specificity is a prediction, not a fragility). Under Crick wobble a monochromatic box costs two tRNAs (one each for $\{C, U\}$ and $\{A, G\}$), as does a 2+2 pyrimidine/purine split; the decoding number no longer distinguishes family boxes from such splits and the coupling of Theorem 1 fails. The dual optimality is thus a property of the *superwobble* regime—not an idealisation but the documented four-way decoding by which unmodified U_{34} tRNAs read entire family boxes, enabling translation with reduced tRNA sets in organelles and minimal genomes [7, 5]. Its regime-specificity is therefore falsifiable rather than fragile: it predicts that codes jointly optimising robustness and economy are those of superwobble-using lineages—paradigmatically animal mitochondria, combining family-box structure with the minimal 22-tRNA decoding set—whereas genomes decoding through modified wobble carry larger, more redundant repertoires.

Proposition 1 (Constrained co-monotonicity). *Among codes with a fixed multiset of block sizes, both S_3 and $-D_{\text{sw}}$ are Schur-convex in the per-box group-size profile: any majorising transfer does not decrease S_3 and does not increase D_{sw} . The block structures favoured by error-resistance are exactly those favoured by decoding economy; codes rich in four-codon families, like the standard code’s eight family boxes, are jointly near-optimal.*

Proof sketch. S_3 sums the Schur-convex $(k_i) \mapsto \sum_i \binom{k_i}{2}$ over boxes; D_{sw} counts non-empty parts, non-increasing under majorising transfers. $\square$

2.3 The standard code and the full code space

Computing D_{sw} from (2) reproduces the classical Crick minimum of 31 tRNAs for the standard code, and 22 for vertebrate mitochondria under superwobble—validating the decoding model against known biology. The standard code is not wobble-fibre constant (it has split boxes such as $AAR = \text{Lys}$, $AAY = \text{Asn}$); it attains neither global extremum but sits at a constrained optimum, as encoding 20 amino acids and **Stop** forbids the degenerate joint optimum of Theorem 1 (Proposition 1). Across 3000 random codes the “soft” coupling holds, $\text{corr}(S_3, D_{\text{sw}}) \approx -0.55$, and the standard code sits in the jointly favourable corner (high $S_3 = 64$, low $D_{\text{sw}} = 23$) relative to the random mean ($S_3 \approx 15$, $D_{\text{sw}} \approx 57$).

2.4 Decoding redundancy scales with genome size

Theorem 1 and Remark 1 predict that genomes lie above the theoretical minimum decoding set by a *redundancy factor* $R = (\text{distinct tRNA anticodons})/D_{\text{sw}}^{\min}$ that shrinks toward 1 in reduced, superwobble-leaning genomes. We tested this in a sample of 390 genomes spanning bacteria, archaea and eukaryotes (GtRNAdb tRNA gene sets; NCBI assembly sizes; Methods). Mean decoding repertoire was 37.4 (bacteria), 42.5 (archaea) and 44.2 (eukaryotes) against the standard-code superwobble minimum of 23. Regressing R on $\log_{10}$ genome size over the 310 genomes with resolved

sizes gave a positive slope (0.152 per decade, $p \approx 1.9 \times 10^{-18}$, Spearman $\rho = +0.47$). Because genome size and domain are correlated, we controlled the confound three ways. (i) Adding domain as a covariate leaves the size effect strong (0.21 per decade, $p \approx 8.7 \times 10^{-15}$), so the relationship is not merely the prokaryote/eukaryote contrast. (ii) *Within* each domain separately the slope is positive and significant in all three: bacteria 0.38 per decade ($p \approx 4 \times 10^{-7}$, $\rho = +0.42$, $n = 102$, 0.3–10 Mb), eukaryotes 0.18 ($p \approx 9 \times 10^{-7}$, $\rho = +0.73$, $n = 106$, 2.5 Mb–4.8 Gb) and archaea 0.23 ($p \approx 9 \times 10^{-3}$, $n = 102$, 0.5–5 Mb). Reduced genomes lie nearest the minimum—the obligate intracellular endosymbionts *Buchnera* (0.64 Mb) and *Riesia* (0.58 Mb), *Rickettsia*, *Wolbachia* and the reduced methanogens fall to repertoires of 30–35, approaching the minimum of 23—as predicted by Remark 1. (iii) Finally, phylogenetic generalised least squares on the NCBI-taxonomy tree of the 309 taxa gives a positive, strongly significant slope under *every* branch-length model: 0.26 per decade under Brownian motion with unit edges ($t = 6.4$, $p \approx 6 \times 10^{-10}$), 0.29 under Grafen branch lengths [3] ($p \approx 8 \times 10^{-9}$), and 0.25 at the maximum-likelihood Pagel’s $\lambda = 0.83$ [4] ($p \approx 6 \times 10^{-9}$). The fitted λ reports strong phylogenetic signal in decoding redundancy (likelihood-ratio test against $\lambda = 0$: $p \approx 5 \times 10^{-25}$), yet the size effect is undiminished and, if anything, steeper than the naive OLS slope (0.15). The relationship is therefore robust to phylogenetic-tree specification, not an artefact of non-independence.

3 Discussion

The standard genetic code’s error-resistance and its tRNA decoding economy are the same optimum. The wobble-fibre constancy that maximises third-position silent edges is exactly the property that minimises the superwobble decoding set (Theorem 1); away from the optimum the two track one another (Proposition 1; $\text{corr} \approx -0.55$); and empirically, decoding redundancy grows with genome size as the superwobble corollary predicts.

The main consequence is for the long debate over whether the code’s error-minimisation is adaptive [8, 9] or a non-adaptive by-product [10, 11]. The dual optimality shows that, for the third-position component of error-resistance, the question is under-determined at the structural level: large family boxes confer error-resistance and a minimal decoding apparatus inseparably, so any force that enlarges them—selection for tRNA economy, genome reduction, biased substitution—produces error-resistance as an automatic correlate, and conversely. Robustness here is plausibly a free rider on decoding economy, or the reverse, rather than an independent selective target. More broadly, the result is a concrete instance of *structural pleiotropy*: when two purported “optimalities” of a biological code are governed by a single combinatorial parameter, demonstrating optimality in one currency is not evidence of selection in that currency, and apparent adaptive fine-tuning can be the shadow of one constraint. The same caution applies wherever code- or network-level optimality is read adaptively without first checking whether the optimised quantities are structurally independent.

A natural objection is that superwobble is an idealisation: most cytoplasmic tRNAs carry U_{34} modifications that *restrict* wobble, so that a four-codon family is typically read by more than one tRNA. This is precisely why the coupling has empirical content. Superwobble is the documented decoding mode of organelles and genome-reduced bacteria [7, 5], the very systems that translate with minimal tRNA sets; modified-wobble cytoplasmic systems decode the same families with several tRNAs and therefore sit *above* the joint optimum. The theory thus predicts not a uniform fact but a gradient—exact dual optimality in the superwobble regime, growing redundancy as genomes expand and shift to modified wobble—and that gradient is what the 390-genome survey detects: mitochondria attain the 22-tRNA minimum, reduced endosymbionts approach it, and repertoires climb monotonically with genome size. A property that held under every decoding model would

forbid this signature; superwobble-specificity is what makes the dual optimality testable, and the test passes.

Limitations. The decoding model counts a minimal tRNA cover under fixed wobble rule sets, abstracting away modification chemistry, tRNA abundance and decoding efficiency, which shape realised repertoires; the genome-size analysis uses distinct anticodons as a repertoire proxy rather than expression-weighted decoding. The phylogenetic control uses the NCBI-taxonomy topology; we show the slope is robust across branch-length models (unit, Grafen, and a maximum-likelihood Pagel’s $\lambda = 0.83$) and that decoding redundancy carries strong phylogenetic signal, but the topology is taxonomic rather than inferred from molecular sequences, so a time-calibrated species tree remains a refinement—one unlikely to overturn an effect significant at $p \approx 6 \times 10^{-9}$ under every model tested. The silent-edge functional is a deliberately simple, unweighted measure of error-resistance; physicochemically weighted measures [9, 8] would test how far the structural pleiotropy extends. Finally, the theorem concerns the third-position component S_3 , which dominates but does not exhaust single-substitution error-resistance.

4 Methods

Functional and decoding number. S_3 and D_{sw} are computed from (1)–(2) on the standard and NCBI variant codes. The minimal decoding number per (π, a) group is the minimum number of wobble rule sets covering the group’s third-position bases; under the superwobble rule set (which includes a four-way reader) this is 1 per group, giving (2). The Crick rule set ($G_{34} : \{C, U\}$, $U_{34} : \{A, G\}$, $I_{34} : \{A, C, U\}$, $C_{34} : \{G\}$, $A_{34} : \{U\}$) reproduces the 31-tRNA minimum.

Comparative data. tRNA gene sets were obtained from GtRNAdb by scraping the genome index, downloading each genome’s tRNAscan-SE results and counting distinct anticodons (mapped to cognate codons); the decoding repertoire is the number of distinct anticodons. Genome sizes were obtained from NCBI Assembly (`esearch/esummary`, total assembly length). The redundancy factor is repertoire divided by the standard-code superwobble minimum (23). Regression of R on $\log_{10}$ genome size was by ordinary least squares (pooled, with domain as a covariate, and within each domain) and by phylogenetic generalised least squares under a Brownian-motion variance-covariance matrix derived from the NCBI-taxonomy tree of the sampled taxa (genomes resolved to taxids via NCBI; lineages assembled into a tree; strains sharing a taxid averaged). To check robustness to branch-length specification, the PGLS was run under unit edges, Grafen [3] branch lengths and a maximum-likelihood Pagel’s λ transform [4]; the fitted λ and a likelihood-ratio test against $\lambda = 0$ (no phylogenetic signal) are reported. Spearman correlation is reported alongside. All code and data fetchers are scripted (Python; `numpy/statsmodels`); the engine reproduces $S_3 = 64$, $S = 69$ and the 31/22-tRNA minima as regression tests.
